## **DEDICATION**

This work is dedicated to my late father, Atanda Adeyinka, to my mother, Atanda Serifat and the entirety of my loving family for their immeasurable love, moral and financial support.

## **ACKNOWLEDGEMENT**

First and foremost I am grateful to Allah (SWT), the Lord of the worlds, for giving me life to accomplish this far. To Him belongs all praise in the Heavens and on Earth.

I am heartily grateful to my supervisor, Dr Sulaiman Al-Khattaf, whose encouragement, guidance and support from the initial to the final level enabled me to develop an understanding of the subject. I would like to thank other members of my committee, Dr. Nabil Al-Yassir for his numerous contributions of his expertise and Dr. Mohammed Ba-Shammakh for the assistance he provided at all levels of the research project. I would like to thank Mr. Mariano Gica who greatly helped out on the experimental work.

To my parents, brothers (Hakeem, Nurudeen), and sister (Anifat), I am deeply appreciative of your patience, encouragement and love throughout the study.

I also want to offer my regards and appreciation to all of those who supported me in any respect during the completion of the project.

In conclusion, I recognize that this research would not have been possible without the financial assistance of KACST, the Center for Refining and Petrochemicals, King Fahd University of Petroleum & Minerals Graduate Studies (Graduate Research Assistanship), and the Department of Chemical Engineering.

## THESIS ABSTRACT

**Name:** ATANDA LUQMAN ABIOLA

**Title of Study:** ETHYLBENZENE DEHYDROGENATION TO STYRENE  
OVER MESOPOROUS MIXED OXIDE CATALYSTS:  
SYNTHESIS, CHARACTERIZATION AND KINETIC  
MODELING

**Degree:** MASTER OF SCIENCE

**Major Field:** CHEMICAL ENGINEERING

**Date of Degree:** May, 2011

A steamless process for ethylbenzene dehydrogenation to styrene was studied in a fluidized bed reactor over mesoporous mixed oxides based catalysts. Experimental runs were carried out over hydrotalcite and  $\text{Fe}_2\text{O}_3$  supported on  $\text{Al}_2\text{O}_3$  catalysts in a riser simulator at different operating conditions. The reaction temperature was varied in the range of 350–550 °C, and the reaction time was varied from 5-20 seconds. Both catalyst systems were significantly active for the ethylbenzene dehydrogenation reaction. This behaviour is ascribed to the high surface area and porosity of the catalysts which enhanced the diffusion of reactant molecules into and the reaction products out of the catalyst pores. This is also coupled with the effective catalytic cycle due to mixed acidic-basic sites and reduction-oxidation reaction of the active specie. A kinetic model was derived to better understand the reaction behaviour. Modeling of the experimental results was based on both reactant conversion (RC) and time-on-stream (TOS) models.

## THESIS ABSTRACT (ARABIC)

### ملخص البحث

الاسم: لقمان اتاندا ابيولا

عنوان البحث: اعادة هدرجة ايثيل البنزين الى الاستيرين فوق الحفازات: اصطناع و نموزج حركي

الدرجة: ماجستير العلوم

المجال العام: الهندسة الكيميائية

تاريخ منح الدرجة: مايو 2011

تمت دراسة انتاج الاستيرين في مفاعل الطبقة المتميعه عن طريق اعادة هدرجة ايثيل البنزين بدون بخار الماء تم اجراء التجارب باستخدام حفازات الهيدروتالسيت و اكسيد الحديد المدعم بالالومنيا في مفاعل تجريبي رافع و تحت ظروف تشغيل مختلفه تم دراسة مدى درجة حرارة التشغيل بين 350 و 550 درجة مئوية بزمن تفاعل من 5 الى 20 ثانيه تحليل ناتج التفاعل بواسطة كروماتوغرافيا الغاز اظهر ان الناتج الرئيس هو الاستيرين و وجد ان نوعي الحفاز نشطان لاعادة هدرجة ايثيل البنزين هذا النشاط يعزى لمساحة السطح الكبيره و النفازيه للعوامل الحفازة التي تساعد على تحسين انتشار جزيئات المتفاعل الداخلة لمسامات الحفاز بالاضافه الى جودة دورة الحفاز نسبة لوجود نقاط نشطة حامضيه و قاعديه و تفاعل الاكسده و الاختزال الدوري للنقاط النشطة تم تطوير نموزج لحركية التفاعل لفهم ميكانيكية التفاعل بناء على معدل تحول المتفاعلات الى نواتج و نموزج زمن التفاعل الداخلي

## **CHAPTER 1**

### **1.0 INTRODUCTION**

#### **1.1. Background**

Styrene is one of the most important monomers in modern petrochemical industry. The market has grown from around 20 million tons in 2000 and is expected to reach around 28 million tons in 2010 [1]. However, prior to World War II, the styrene industry, which uses ethylbenzene as a starting material was relatively insignificant. The tremendous demand for synthetic styrene – butadiene rubber (SBR) during the war prompted accelerated technology improvements and capacity expansion. The styrene process was developed in the 1930s by BASF (Germany) and Dow Chemical (USA) and this effort have led to the construction of several large-scale factories, and styrene production became a significant industry.

Styrene is a basic building block in making a variety of materials, most recognizable is polystyrene. Other materials include acrylonitrile-butadiene styrene (ABS) plastic, styrene-acrylonitrile (SAN) plastic, styrene-butadiene rubber (SBR), unsaturated polyester resins and expanded polystyrene foam (EPS). These materials can further be transformed to produce variety of products across a wide range of industries as there is no direct end use for styrene. Products made from styrene are of high performance, durable, safety, value and high quality [1]. Many of these products offer very good insulation qualities and the ability to be recycled. These products range from

packaging materials to a myriad of consumer electronics, construction, transportation and medical applications. Therefore, styrene production is done indeed in a large scale that follows those of ethylene, propylene and vinyl chloride. The global styrene capacity in 2008 is 26million tons per year. The global distribution of the styrene production facilities is shown in Figure 1.1a. while global distribution of styrene consumption by product is shown in Figure 1.1b [2].

Figure 1.1a. Global styrene capacity (2008)

Figure 1.1b. Global styrene consumption (2008)

## **1.2. Main Industrial Technologies for styrene production**

Industrially, styrene is produced mainly through two process routes: dehydrogenation of ethylbenzene and co-production with propylene oxide in a process known as SM/PO (Styrene Monomer/Propylene Oxide) or POSM. Both routes use ethylbenzene (EB) as the intermediate, EB is first made by the catalytic alkylation of benzene with ethylene, using either aluminium chloride or, more recently, zeolite catalysts [3]. Ethylbenzene and styrene units are almost always installed together with matching capacities because nearly all of the ethylbenzene produced commercially is converted to styrene. Alkylation is exothermic and dehydrogenation is endothermic, as a result energy economy in a typical ethylbenzene-styrene complex is achieved by integrating the energy flows of the two units.

### **1.2.1. Catalytic Dehydrogenation of Ethylbenzene**

This route accounts for 90% of the total world production. Dehydrogenation of ethylbenzene can be run industrially using either multiple bed adiabatic or tubular isothermal reactors in which the reactants are passed over the catalyst bed employing radial or axial flow. In this process, EB is dehydrogenated to styrene in the presence of potassium promoted iron oxide catalyst and a super-heated steam was fed to supply the heat of endothermic dehydrogenation and further to suppress the coking. Formations of by-products are suppressed by reducing the partial pressure of the reaction. Generally, adiabatic dehydrogenation in multiple bed reactors is preferred but both methods are used. This process is employed by the Lummus/UOP Classic Smart [4]. Typical conversions up to 69%, styrene selectivity of more than 97 mol% and a styrene monomer

purity of 99.85 wt% are achieved. Flow scheme of a typical Lummus/UOP adiabatic ethylbenzene dehydrogenation plant is shown below:

Figure 1.2. Lummus/UOP Classic SM process of adiabatic ethylbenzene dehydrogenation plant

To eliminate the costly interstage reheating and reduce superheated steam requirements, the technology has been modified and improved to Lummus/UOP Smart SM process [4]. This modified technology combines oxidative reheat technology with adiabatic dehydrogenation technology. In this approach, heat needed for the dehydrogenation reaction is generated by controlled combustion of hydrogen. By removing hydrogen from the reaction mixture, the reaction equilibrium is shifted towards higher EB conversion. Increased conversion up to 80 % is achieved without compromising the purity of the styrene monomer.

### 1.2.2. Styrene and Propylene Oxide (SMPO) Process

This process was discovered in the 1970's by Halcon and improved by Royal Dutch SHELL [5]. The coproduction of propylene oxide (PO) and styrene (SM) route is complex and capital-intensive in comparison to dehydrogenation of ethylbenzene. The process includes three reaction steps: oxidation of ethylbenzene to ethylbenzene hydroperoxide (EBHP), epoxidation of ethylbenzene hydroperoxide (EBHP) with propylene to form  $\alpha$ -phenylethanol and propylene oxide, and dehydration of  $\alpha$ -phenylethanol to styrene.

Figure 1.3. Simplified flow diagram of the SMPO process

The SMPO process is cleaner and much less energy intensive than the conventional dehydrogenation route (less by-products). Its major drawback is that production of styrene is limited by the amount of propylene oxide that can be sold [6]. The process flow diagram is shown in Figure 1.3

### **1.3. Other Technologies**

Other technologies in the manufacture of styrene include:

#### **1.3.1. Styrene production from ethane and benzene**

This is a joint technology developed by Snamprogetti S.p.A and Dow [7, 8]. It is an alternative dehydrogenation process that use ethane rather ethylbenzene as feed to the process. Ethane and ethylbenzene from the alkylation unit is fed to a circulating fluidized bed reactor system that simultaneously produces styrene and ethylene and allows continuous catalyst regeneration. The dehydrogenation reactor effluent is cooled and separated and the ethylene stream is recycled to the alkylation unit. The catalyst composition suitable for this process consists of microspheroidal catalyst particles of Gallium/Platinum/Potassium supported on alumina with a silica binder. This novel route of styrene production integrates the processes of producing ethylene, ethylbenzene and styrene. Another advantage of the process is the recovery of commercial grade hydrogen as a by-product.

#### **1.3.2. Styrene production from methanol and toluene**

The side chain alkylation of toluene with methanol is a potential alternative technology to produce styrene. Direct side alkylation of toluene over basic zeolites is an interesting reaction, considering the industrial importance of its products, especially

ethylbenzene and styrene [9]. It is generally accepted that zeolites with some basicity catalyze side-chain alkylation to styrene which is subsequently hydrogenated to ethylbenzene while those which compose of acid sites accomplish only ring alkylation. Styrene monomer production via alkylation of toluene occurs in gas phase at condition 420 °C, 4-7 bar with the presence of zeolite X and Y catalyst. The reactions occur in a two parallel reaction that produces styrene and ethyl benzene. The raw material being used are liquid toluene and liquid methanol that are preheated to 420 °C before enter the reactor. The catalyst used in this process has high styrene selectivity so that the styrene yield could reach 85%. This process has been claimed to be economically attractive offering the advantage of lower raw material cost compared with the traditional process [10].

Other processes for the production of styrene are: side-chain chlorination of ethylbenzene, styrene extraction from pyrolysis gasoline (Toray's STEX process) and oxidative conversion of ethylbenzene to  $\alpha$ -phenylethanol via acetophenone and subsequent dehydration of the alcohol [11].

#### **1.4. Motivation**

Research and development of new catalysts, reactor designs, and process routes has been continuously pursued to achieve process improvement. Recently a good collaboration has been done between catalyst research and process development, and such collaboration evidently enabled the development of new much energy-saving catalytic process, to decrease the cost unit of raw materials and finally to enhance the production capability. BASF and DOW processes composed of multitubular fixed-bed reactor have been known as industrial processes, whereas Lummus and Badger (Stone &

Webster, Shaw group) processes composed of radial-flow type reactor are recently used due to its adiabatic character applicable for the large scale production. Now the size of reactor is increasing and new plants possessing 500,000~600,000 t/y productivity are under construction. SMART process developed by UOP is known by its unique technology combining dehydrogenation and oxidation; hydrogen formed by dehydrogenation was consumed by reacting with oxygen gas. This favors thermodynamic equilibrium to styrene production and simultaneously steam and heat are supplied to the reactor. Actually, this process is frequently adopted when the reactor is reformed to increase the productivity.

In view of this, a plausible new catalytic process of ethylbenzene dehydrogenation to improve styrene production will be developed which is going to be a steamless process without the promotional role of potassium. Development of this process depends primarily on the development of highly efficient catalysts, which will be achieved by fundamental studies of the catalyst preparations as well as the catalytic reactions involved in the process. For the dehydrogenation at a low temperature, highly dispersed Fe catalyst derived from Mg/Fe/Al ternary hydrotalcite precursors is a promising candidate due to its high activity. Alumina-supported metal oxides with well ordered mesoporosity are also a choice for the dehydrogenation process. We aim to optimize the catalysts by modifying the preparative conditions and the metal compositions in the catalysts. The catalytic process will make use of a fluidized bed reactor instead of the more commonly used fixed bed reactors. A fluid bed process can offer several potential advantages over the fixed bed process. These include enhanced reactant-catalyst contact resulting in higher reaction rates and hence shorter reaction times, uniform product quality as a result of extensive

bed mixing and heat distribution. It also enhances easy and timely catalyst regeneration in contrast to the fixed bed process where catalyst regeneration is often laborious, expensive and time consuming [12]. The reaction will be studied under several conditions (reaction times and temperatures) for catalyst testing and kinetic modeling of catalytic reactions. Finally, by optimizing the reaction conditions, highly efficient process can be established in the dehydrogenation of ethylbenzene to styrene, as well as lead to an energetically and environmentally benign chemical production.

### **1.5. Thesis Objectives**

The main objectives of this work are of two-fold; i) to develop highly efficient catalysts for dehydrogenation of ethylbenzene to styrene, and ii) kinetic studies of the reaction.

The detailed specific objectives are as follows:

#### **1.5.1. Synthesis and characterization of hydrotalcite and mesoporous iron oxide-alumina based catalysts**

- i. Mg/Fe/Al hydrotalcite precursor is selected as a base catalyst which is to be modified by Cobalt, Manganese and Nickel.
- ii. Facile synthesis of mesoporous alumina on which iron oxide shall be doped.
- iii. Determination of the physico-chemical properties of the catalysts through some characterization techniques.

#### **1.5.2. Catalysts Test Performance**

The prepared catalysts' activity and selectivity will be determined for the dehydrogenation process. Fluidized bed reactor will be used for the catalytic dehydrogenation of ethylbenzene at short reaction time (5 – 20 s) and reaction

temperature (350 – 550 °C) lower than that used industrially. It is expected that the short reaction times will limit the tendencies of undesired reactions from taking place and the relatively low temperature will prevent the occurrence of thermal reactions.

### **1.5.3. Kinetic modeling**

Key to any process development is the availability of important design parameters such as the activation energy of the reaction, rate constants, etc. This will involve the following:

- i. Proposing different possible reaction models
- ii. Fitting experimental data into the proposed models to check the suitability of the models
- iii. Determination of kinetic parameters; apparent activation energies, apparent reaction rate constants.

## **1.6. Thesis Outline**

**Chapter 2** presents a literature review on dehydrogenation of ethylbenzene. An overview of its reaction mechanism is given, catalyst composition and deactivation. Challenges facing the commercial catalyst used for the dehydrogenation process were discussed, and what has been done so far in terms of catalysts development to tackle these challenges. Overview of the kinetic studies of the reactions involved was also reviewed.

**Chapter 3** deals with the experimental section. Description of the equipment used for the experimental set-up is given as well as the procedures adopted. This chapter also explains catalyst synthesis, characterization and evaluation.

**Chapter 4** focuses on the results of the experimental work. Discussion of the effects of reaction conditions (temperature and time) are given in details. In addition, a detailed

kinetic modeling of the reaction over all the catalysts (hydrotalcites and mesoporous iron oxide-alumina) is presented starting first with model formulation and then estimation of the kinetic parameters using non-linear regression analysis.

**Chapter 5** gives the summary of our contribution, conclusions and recommendation for future work

## CHAPTER 2

### 2.0 LITERATURE REVIEW

#### 2.1. Introduction

The catalytic dehydrogenation of ethylbenzene is an important reaction used commercially for the production of styrene. The dehydrogenation reaction is thermodynamically favored at high temperature and low pressure. The dehydrogenation reaction must overcome the constraint resulting from the fact that energy required to break a C-C bond (245 kJ/mol) is less than the energy necessary to break C-H bond (365 kJ/mol) [13]. Therefore, thermal reaction is not advisable, since it would lead to a predominance of cracking reactions over dehydrogenation reactions. However, in the presence of a suitable catalyst, dehydrogenation can be carried out with minimal C-C bond rupture. Therefore, typical dehydrogenation of ethylbenzene industrially is carried out on iron oxide based catalysts at temperatures above 600 °C. The reaction is highly endothermic ( $\Delta H = 124.9$  kJ/mol) and reversible, therefore steam is used in large amount since; steam plays a prominent role in shifting of the reaction equilibrium towards products, prolonging the catalyst activity and most significantly acts as a heat carrier. The dilution with steam also reduces the potential for the formation of coke [14]. The conversion per pass is generally 60-70%, with styrene selectivity between 93-95%. A simplified reaction scheme of catalytic dehydrogenation of ethylbenzene is shown in Figure 2.1.

Figure 2.1 Reaction scheme of catalytic dehydrogenation of ethylbenzene [15]

The main reaction produces styrene and hydrogen.

In addition to the main dehydrogenation reaction, some side reactions also occur. The most common side reactions are cracking to benzene and ethylene or hydrogenolysis to toluene and methane, and coke formation. Therefore, the main by-products are benzene and toluene [15].

However, the usage of large volume of superheated steam is one of the drawbacks of the present technology. The process involves high consumption estimated to be  $1.5 \times 10^6$  kcal/styrene tone [16] because all the latent heat of condensation of steam is lost at the liquid-gas separator during the process. Therefore, efforts are underway in reducing the steam/hydrocarbon ratio to molar values less than 6, essentially through modifications in catalyst composition to save energy and reach higher styrene conversion levels.

## 2.2. Catalysts for Ethylbenzene dehydrogenation

The use of a suitable catalyst allows high reaction rates and, above all, high selectivity. The principal catalytic system that has dehydrogenation activity for ethylbenzene is essentially potassium promoted iron oxide, containing chromium oxide (Shell 105). Among the most common promoters added to iron oxide, the alkali oxides have the most noticeable effects on catalytic activity and selectivity. Other metals are used as supplementary promoters, such as, cerium, tin, calcium, molybdenum, magnesium, titanium and others. Potassium-promoted iron oxide is uniquely superior to

any other known catalyst for the dehydrogenation of ethylbenzene in the presence of steam [17], particularly efficient with respect to both selectivity and activity. Promotion of iron oxide with potassium enhances the activity of iron oxide by an order of magnitude and reduces the formation of carbonaceous surface deposits or coke that deactivates the catalysts [14,18-19]. A study of the structure and composition of the catalysts established the promotional role of potassium to consist of the formation of  $\text{KFeO}_2$ , which constitutes the active phase. Muhler et. al. [20] also confirmed the active phase to be a thin layer of  $\text{KFeO}_2$  supported on a solid solution of  $\text{K}_2\text{Fe}_{22}\text{O}_{34}$  in  $\text{Fe}_3\text{O}_4$ . The existence of the ternary  $\text{K}_2\text{Fe}_{22}\text{O}_{34}$  serves as storage medium from which the active surface is continuously supplied with a near monolayer coverage of potassium ions in an environment of  $\text{Fe}^{3+}$  ions. Lee and Holmes [21] suggested that potassium increase activity by encouraging electron transfer at the solid-gas interface. Potassium further stabilizes the catalyst against reduction [22] and supports the removal of coke. The formation of well dispersed  $\text{K}_2\text{CO}_3$  is believed to be the active center for carbon gasification [23]. However, a major setback of potassium is its deactivation with time which is caused by migration and susceptibility to poisoning by halides and residual organic chloride impurities [14]. Small amounts of other promoters are added to favor the formation and stability of the active phase under reaction conditions at lower steam to hydrocarbon ratios. Aluminum and chromium act as structural promoters and increase the lifetime of the catalysts. Titanium increased the number of active phase  $\text{KFeO}_2$  and improves the dispersion of  $\text{CeO}_2$  [24], while the addition of both Ce and Mo improved the catalyst composition, increasing both activity and selectivity [19]. Addition of alkaline earth oxides especially  $\text{MgO}$  to the potassium promoted iron oxide catalysts improved its activity and stability [25].

### 2.3. Catalyst deactivation

Several forms of catalyst deactivation have been identified for this type of catalysts under ethylbenzene dehydrogenation. The catalyst slowly deactivates and typically needs to be replaced every 1-2 years. The major cause of catalyst deactivation is carbon deposition. The temperatures and low pressures necessary to achieve high equilibrium conversions are conducive to the rapid coke formation. Steam is continuously used during the reaction to aid gasification of the coke to substantially reduce coke formation, via the reaction:

Formation of CO<sub>2</sub> from the above reaction blocks the active sites of the catalyst leading to the second type of catalyst deactivation. These two forms of deactivation are considered reversible because both, coke and adsorbed CO<sub>2</sub>, can be eliminated by the same steaming treatment. However, in addition to this reversible deactivation, other irreversible phenomena occur in these catalysts. The most important one is the loss or redistribution of potassium from the active phase, KFeO<sub>2</sub>. This changes the composition of the catalyst leading to a potassium rich core and a potassium depleted shell in each catalyst pellet or extrudate. This deactivation phenomenon alters the catalytic activity of the catalyst by increasing its acidity [14]. This consequently favors cracking reactions to benzene and toluene. Physical degradation and reduction of the catalyst by the hydrogen formed during the reaction are other forms of catalyst deactivation [18,26]. A comprehensive investigation of the catalyst life cycle was studied by Muhler et. al. [20], and the authors proposed a model shown below:

Figure 2.2. Schematic life cycle of a prototype catalyst without any promoter additives [20]

## 2.4. Reaction Kinetics and Mechanisms

Kinetics of ethylbenzene dehydrogenation has been extensively investigated with the aim of obtaining a kinetic model useful for both industrial application and interpretation of the reaction mechanism. Kinetic models based on pseudo-homogeneous reactor model have been used to determine intrinsic reaction rates [27,28]. A reaction scheme composed of six independent reactions: the main reaction, i.e., ethylbenzene to styrene, and five side reactions were proposed. The rate constants thus were effective but not intrinsic. Therefore, a rigorous heterogeneous model has been developed and used to extract intrinsic rate constants based on dusty gas models accounting for diffusion and reaction in the catalyst pellets [29]. Carrà and Forni [30] performed kinetic studies in the temperature range of 770–900 K over the industrial catalyst, Shell 105. The intrinsic rate of styrene formation was developed, based upon unimolecular Langmuir-Hinshelwood mechanism, where the reaction rate depends on the adsorption-desorption equilibrium of ethylbenzene and styrene. It is believed that water does not take part in the reaction itself i.e. not involved in the rate determining step of the reaction mechanism, but acts purely as inert diluents agent. Hirano [18-19, 31] investigated the kinetics over various iron oxide catalysts in a differential reactor. The rate of styrene formation was independent of the partial pressure of steam and of ethylbenzene. However, styrene addition to the ethylbenzene feed decreased the rate of styrene formation, which confirmed the earlier suggestion of Carrà and Forni that preferred adsorption of styrene can lead to site-blocking effect by the product. Dittmeyer et. al. [32] studied the reaction kinetics of ethylbenzene dehydrogenation in a gradientless recycle reactor. The rate equations were developed based on the Langmuir-Hinshelwood-Hougen-Watson (LHHW) type formula

for the main reaction and the power law for the steam reforming reactions. The authors found out that the formation of styrene and toluene were suppressed due to controlled  $\text{CO}_2$  addition and production of  $\text{CO}_2$  was attributed to the steam reforming of ethylbenzene and  $\text{CH}_4$ . A mechanistic catalyst model neglecting side reactions towards benzene and toluene was derived by Schüle et al. [33]. The model assumes overall conversion consists of individual steps adsorption, surface reaction and desorption. Another single-step reaction considered is the gas-solid reactions related to formation of coke and phase transformation of iron oxide. More recently Lee and Froment [34] developed a set of intrinsic rate equations for a commercial potassium-promoted iron catalyst based on Hougen-Watson model. The model was applied in the simulation of the dehydrogenation in industrial multibed adiabatic reactors which accounts for thermal radical-type reactions, internal diffusion limitations, coke formation, and gasification. Kinetic studies on model catalysts by Coulter et al. [35] showed similar apparent activation energies for K-promoted and unpromoted iron oxide catalysts. They suggested that potassium only increases the number of active sites, but does not change their nature.

Several authors have investigated the reaction mechanism of dehydrogenation of ethylbenzene on the Fe-K mixed oxide catalyst. An infrared spectroscopy study by Addiego et al [36] observed that ethylbenzene dehydrogenation from which styrene is formed was bonded to the catalyst surface through the vinyl group, whereas styrene adsorbed from the gas phase was bound via the aromatic ring. Miura et al. [37] investigated dehydrogenation of alkylbenzenes over an  $\text{Fe}_2\text{O}_3$ -  $\text{K}_2\text{CO}_3$ -  $\text{Cr}_2\text{O}_3$  catalyst by means of isotope exchange experiments. According to them, dissociation of  $\alpha$ -hydrogen is the first step followed by dissociation of  $\beta$ -hydrogen, which is the rate-determining

step or post rate-determining step. They concluded that the  $\alpha$ -hydrogen is dissociated as a proton on a basic site. Dulamiță et al. [38] proposed a mixed acid-basic and reduction-oxidation mechanism based on the kinetic study on the same catalyst as ref. 37; a formation of  $\pi$ -adsorbed intermediate on  $\text{Fe}^{3+}$  acid centers, followed by elimination of two hydrogen ions from two C-H ethylic groups on basic centers with electrons transfer to  $\text{Fe}^{3+}$  to form styrene and  $\text{H}_2$ . Oliveira et al. [39] proposed acid-base mechanism to operate to adsorb ethylbenzene and abstract the  $\beta$ -hydrogen in the ethylbenzene dehydrogenation over Fe-MCM-41.

## 2.5. Catalyst development for ethylbenzene dehydrogenation

Improvement of styrene production includes development of high selectivity catalyst and reactor design. The presence of several consecutive reactions is responsible for the typical trade-off between conversion and selectivity to the desired product. Therefore, the main challenges in the area of catalyst development for ethylbenzene dehydrogenation are the development of a catalyst which:

- i. Stabilize the active specie in the absence of potassium promoter and superheated steam
- ii. Possess high surface area
- iii. Minimizes coke formation and catalyst deactivation
- iv. Active and selective towards increased styrene yield

### 2.5.1. Hydrotalcites

Hydrotalcite-like compounds or more generally speaking layered double hydroxides (LDHs) have the general formula  $[\text{M(II)}_{1-x}\text{M(III)}_x(\text{OH})_2]^{x+}(\text{A}^{n-})_{x/n} \cdot m\text{H}_2\text{O}$  where M(II) is a divalent cation ( $\text{Mg}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Mn}^{2+}$ ), M(III) is a trivalent

cation ( $\text{Fe}^{3+}$ ,  $\text{Cr}^{3+}$ ,  $\text{Al}^{3+}$ ), A is an anion. It is of importance to choose the appropriate ratio of cations and anions in order to obtain a pure HTlc during preparation:  $0.2 \leq x \leq 0.4$  and  $1/n \leq \text{A}^{n-} / \text{M(III)} \leq 1$ , where  $x = \text{M(III)} / [\text{M(II)} + \text{M(III)}]$  [40]. HTlcs are usually carbonate in natural minerals and belong to the class of anionic clays. They are structurally similar to brucite  $\text{Mg(OH)}_2$ ; they are layered materials made of positively charged two-dimensional sheets of mixed hydroxides with water and exchangeable charge-compensating anions [40,41].

Figure 2.3. Structure of hydrotalcite

HTlcs are gaining considerable interest in several technological fields, particularly for base-catalyzed reactions. This is because the catalysts contain various transition metal cations as the catalytically active species well dispersed on the basic support materials. Their properties and applications have been the subject of detailed reviews, [40-43] and many publications have provided examples of their practical uses. Isomorphous substitution of divalent cations by trivalent ones generates positive charges on the layers, which are compensated by anions located in the interlayer region. The possibility of accommodation of cations of different natures in the sheets, atomic scale homogeneity, possibility of intercalation of several types of anions (inorganic, organic, organometallic, polyoxometalates) and formation of mixed oxides under thermal treatment makes HT applicable to wide range of applications. They are usually activated by thermal decomposition to serve as precursors for mixed oxide catalysts which offer unique basic properties that make them very attractive for catalytic applications. The resultant oxides upon calcinations exhibit high surface area, high thermal stability and highly homogeneous metal dispersion [40] which improves their catalytic performance. Moreover, they are potentially recoverable and recyclable [44]. In addition to the basic sites, acid sites or acid-base pairs on HTs also influence catalytic performance. Acid-base sites on mixed oxides are highly active sites for many reactions. Acid-base properties of Mg-Al mixed oxides are governed by the Mg/Al molar ratio, calcination temperature and preparation condition [45]. A further improvement to the catalysts has been obtained by modification of the HTlcs through the addition of other elements. Mg/Fe/Al mixed oxides prepared from Mg-Al(Fe) HTs has been reported to effectively catalyze the dehydrogenation of ethylbenzene [46]. The high catalytic performance was attributed to

the formation of partially reduced iron oxides on the surface of catalyst and to the high surface area along with the porous structure, which originated from the Mg/Fe/Al hydrotalcite structure in the precursors. The main phase was identified as the formation of periclase  $\text{Mg}(\text{Fe},\text{Al})\text{O}$ . Catalytic tests of the  $\text{Mg}_2\text{Fe}_x\text{Al}_{1-x}$  mixed oxides catalysts showed that the styrene conversion increased with increasing the iron content up to  $x = 0.75$  and then decreased, while the selectivity was the highest at  $x = 0.25$  (Figure 2.3). The optimum temperature for the reaction was  $550\text{ }^\circ\text{C}$ , which was lower than that used in the commercial process. The ethylbenzene conversion of 60% and the styrene selectivity of 95% were kept for 3 h over  $\text{Mg}_3\text{Fe}_{0.5}\text{Al}_{0.5}$  mixed oxide catalyst at  $550\text{ }^\circ\text{C}$ . After the reaction for 3 h, the iron species on the catalyst was partially reduced to the valence state between  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ .

Figure 2.4. The dehydrogenation of ethylbenzene over  $\text{Mg}_2\text{Fe}_x\text{Al}_{1-x}$  mixed oxides catalysts [46]:

○ethylbenzene conversion; ●styrene selectivity; ■benzene selectivity; ▲toluene selectivity.

A further study to elucidate the role of MgO as basic support for this catalyst showed that the mixed acid-basic and reduction-oxidation reaction on the  $\text{Mg}^{2+}\text{-O}^{2-}\text{-Fe}^{3+}$  active species leads to an effective catalytic cycle, responsible for its high catalytic performance [47]. MgO effectively initiated dehydrogenation by  $\text{H}^+$  abstraction of EB on the basic site, and proceeded by the accelerated reduction-oxidation of  $\text{Fe}^{3+}$  active species. Furthermore, improvement of the activity of the  $\text{Mg}_3\text{Fe}_{0.5}\text{Al}_{0.5}$  mixed oxide catalyst can be achieved by optimizing the Mg/Fe/Al metal composition and further by adding the second metal component to the Fe catalyst. This has been proven to be true from a recent study on the activity of various  $\text{FeO}_x\text{-MeO}_y/\text{Mg(Al)O}$  catalysts derived from HTs [48]. Addition of cobalt ( $\text{Me} = \text{Co}$ ;  $\text{FeO}_x\text{-CoO}_y/\text{Mg(Al)O}$ ) improved the activity of the catalyst due to the formation of  $\text{Fe}^{3+} - \text{Co}^{2+}$  (1/1) bimetallic species. This further facilitated the reduction-oxidation of  $\text{Fe}^{3+}/\text{Fe}^{2+}$  and stabilized the active  $\text{Fe}^{3+}$  species.

### 2.5.2. Mesoporous Alumina doped with iron

The importance of alumina as a catalyst or support has been widely recognized. As a support or co-catalyst it is used in many catalytic processes of industrial importance such as isomerization, alkylation, catalytic cracking, hydroforming, hydrodesulfurization of petroleum products [49, 50]. Transition aluminas are disordered crystalline phases formed through the thermal dehydration of aluminum hydroxides and oxyhydroxides [51]. Seven transition alumina phases have been identified which include the  $\gamma$ -,  $\eta$ -,  $\delta$ -,  $\theta$ -,  $\kappa$ -,  $\chi$ -, and the stable  $\alpha$ -alumina phase. Among these,  $\gamma\text{-Al}_2\text{O}_3$  is widely used in catalysis as an active phase and is characterized by having acid sites which determines the activity and selectivity of the catalyst for specific catalytic reactions [52]. The utility of  $\gamma\text{-Al}_2\text{O}_3$

as well as other transition aluminas can also be traced to a favorable combination of textural properties (i.e. surface area, pore volume and pore size). Mesoporous alumina supports with large surface areas, large pore volumes, narrow pore size and suitable surface acidic–basic properties often result in favorable enhancements in catalytic performance [53, 54]. Therefore, synthesis of organized mesoporous aluminas attracted particular research activities in the last decade, which provided new synthetic approaches using novel structure-directing agents. Synthetic approaches such as sol gel, hydrothermal, precipitation, cation-anion double hydrolysis and microemulsion templating methods [55-62], have been used to synthesize mesoporous alumina with a large surface area. However, it has been observed that relatively low thermal instability associated with as-synthesized alumina constituted a major setback. This is because phase transition often occurs during high calcinations temperatures. Recently, a facile synthesis developed by Yuan et. al. [63] has been used to develop a highly ordered mesoporous amorphous and/or crystalline  $\gamma$ -aluminas with high thermal stability and large amount of lewis acid sites. This method has been extended to the development of alumina-supported metal oxides with well-developed mesoporosity, relatively high surface area and crystalline pore walls through one-pot synthesis [64]. A new synthetic procedure for ordered mesoporous  $\gamma$ -alumina with a large surface area has been proposed by Huang et. al., suggested to be catalyst supports in high temperature reactions [65]. Few works have been reported on the use of iron doped alumina catalyst for ethylbenzene dehydrogenation.  $\text{Fe}_2\text{O}_3$  supported on  $\gamma$ -alumina has been suggested to interact with each other to form  $\text{FeAl}_2\text{O}_4$  spinel and stabilize the  $\text{Fe}_2\text{O}_3$  phase [66]. This was in line with the observation of Giecko et. al. [67] and they further proposed that iron aluminates

( $\text{FeAl}_2\text{O}_4$ ) are reducible species formed due to high temperature sintering process. Mimura and Saito [68] suggested that high activity is attainable using coprecipitation method for  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  catalyst and the active sites are composed of iron and aluminium which might be amorphous and/or highly dispersed. Their investigation further shows the effectiveness of  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  for the dehydrogenation of ethylbenzene in the presence of  $\text{CO}_2$ . Lee [14] also suggests that  $\text{Al}_2\text{O}_3$  is effective for EB dehydrogenation in the absence of steam as diluents. However, rare works has been reported on the use of  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  catalyst for non-oxidative or direct ethylbenzene dehydrogenation.

## **CHAPTER 3**

### **3.0 EXPERIMENTAL SECTION**

#### **3.1. Experimental Set-up**

Experimental runs for the dehydrogenation process were carried out in a riser simulator reactor. The reactor was connected to a vacuum box through a four-port valve. The products were removed from the riser simulator at the end of the pre-set reaction period. A time/actuator assembly linked to the feed injection system controlled the four-port valve. The vacuum system was connected to a manually operated six-port sampling valve. This sampling valve was connected on-line to the gas chromatograph. Furthermore, the riser simulator reactor and the vacuum box were equipped with pressure transducers to monitor the pressure during and after the reaction periods. Both the reactor and the vacuum system were supplied by separated heating systems and both were well insulated.

The feed injecting system includes a gas tight syringe connected to switches to control the timer/actuator assembly on the four port valve and the data acquisition system. The data acquisition system allowed monitoring the change of pressure with time from both the reactor and the vacuum box. A four-port valve, controlled by a timer/actuator assembly, was linked to the injection system. A vacuum system was also connected to the manually operated six port sampling valve which allows for sampling injections into the gas chromatograph. Both, the reactor and the vacuum system are

located in temperature controlled ovens. Connections between components are accomplished using heated and well insulated lines. The unit was also equipped with two pressure transducers which allowed for continuous pressure monitoring during the reaction and post-reaction evacuation periods. A schematic diagram of the experimental setup is given in Figure 3.1.

Figure 3.1. Schematic diagram of the riser simulator experimental set-up

### **3.1.1. Riser Simulator**

This novel reactor was invented by de Lasa [69] and it was designed to provide high gas phase circulation rates as well as intense catalyst mixing. In this respect, perfect mixing with the absence of coke profiles and gas channeling can be obtained with all catalyst particles being exposed to the same reaction environment. As mentioned by Pruski et. al. [70], good fluidization is achieved under typical riser conditions and using shaft spinning rates close to 7600 rpm. The riser simulator can be used for several purposes: a) to test industrial catalysts at commercial conditions [71], b) to carry out kinetic and modeling studies for certain reactions, c) to develop adsorption studies [70], d) to use the data of this unit for assessing the enthalpy of cracking reactions. The riser simulator consists of two outer shells, the lower section and the upper section, which allow one to load or to unload the catalyst easily. The reactor was designed in such a way that an annular space is created between the outer portion of the basket and the inner part of the reactor shell. A metallic gasket seals the two chambers with an impeller located in the upper section. A packing gland assembly and a cooling jacket surrounding the shaft provide support for the impeller. Upon rotation of the shaft, gas is forced outward from the center of the impeller toward the walls. This creates a lower pressure in the center region of the impeller, thus inducing flow of gas upward through the catalyst chamber from the bottom of the reactor annular region where the pressure is slightly higher. The impeller provides a fluidized bed of catalyst particles as well as intense gas mixing inside the reactor. A schematic diagram of the riser simulator is shown in Figure 3.2

Figure 3.2a. Schematic diagram of the riser simulator

Figure 3.2b. Cross section of the riser simulator displaying the unit components

### **3.1.2. Gas Chromatograph (GC) System**

The quantitative analysis of the reaction products were carried out online using an Agilent GC equipped with Flame Ionization Detector FID (Agilent Chromatograph Model 6890N), equipped with an HP-INNOWAX capillary column (Polyethylene glycol (PEG)) (length 60 m x internal diameter 0.32 mm x film thickness 0.50  $\mu\text{m}$ ). Helium is used as the carrier gas, while air and hydrogen gases are used for the FID detector. Furthermore, liquid nitrogen is used to facilitate the initial cryogenic operation of the GC temperature program. The liquid nitrogen cools the GC oven to  $-30\text{ }^{\circ}\text{C}$ . The flow of liquid nitrogen is administered by a solenoid valve actuated from the GC's internal oven temperature controller. The integrator allows strip chart recording as well as integration of the GC detector signal. The integrator is connected to the GC via a HPIL instrument network cabling system.

Figure 3.3. Schematic diagram of the gas chromatograph

### 3.1.3 Coke Analyzer

A carbon analyzer multi EA 2000 (Analytikjena) is used. This multi EA 2000 equipped with CS Module is a specially developed system which permits simultaneous or separate determination of the total carbon and total sulphur in samples of solids, pastes and liquids by means of high temperature oxidation in a current of oxygen supplied directly to the unit. It is based on special high temperature ceramics (HTC) technology which renders a catalyst superfluous. By combining the finely tuned non-dispersive infrared gas analysis (NDIR) detection which is selective to CO<sub>2</sub>/SO<sub>2</sub> with the patented Verweilzeitgekoppelte Integration fur TOC-Analysen (VITA) procedure, which takes into account the dwelling time, the analysis possible is very precise. The aliquot of the sample is accurately weighed into the combustion boat and delivered complete into the hot zone of the furnace. There, pyrolysis and oxidation of the sample occurs at a high temperature in the stream of oxygen ( $R + O_2 \rightarrow CO_2 + H_2O$ , where R is a substance with carbon content). The gas produced in the pyrolysis is drawn through a glass tube filled with a specialist desiccant. This desiccation tube also serves as a particle filter, so that no water or dust can get into the detection system of the device. An NDIR detector is used to determine the CO<sub>2</sub> content in the carrier gas. Gases whose molecules are composed of different types of atom possess specific absorption bands in the infrared wavelength range. The concentration of CO<sub>2</sub> is signaled several times per second. An integral over time is created from the series of signals. The integral is proportional to the concentration of carbon in the sample analyzed. A calibration function is then used to calculate the amount of carbon in the sample. The calibrations allows for any changes to flow arising over time because of such factors as the ageing process, dirt getting into flow regulators,

or the desiccants going lumpy, will not automatically necessitate recalibration, which is a positive factor reducing the frequency of desiccant replacement. A small amount of the spent catalyst (0.09-0.1 g) is used for the analysis.

## **3.2. EXPERIMENTAL PROCEDURE**

### **3.2.1. Materials**

All the precursors used in the synthesis of the HT quaternary mixed oxides  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}$  and  $\text{Ni}$ ) and iron doped organized mesoporous alumina catalysts were obtained from Sigma-Aldrich and used as received. The chemical feedstock (ethylbenzene, 99%) was also supplied by Sigma-Aldrich.

### **3.2.2. Catalyst Preparation**

#### **3.2.2.1. Synthesis of hydrotalcite catalysts**

The HT precursors of  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}$  and  $\text{Ni}$ ) catalysts were prepared by co-precipitation of metal nitrates, following the method by Miyata and Okada [72] after minor modifications. An aqueous solution containing the nitrates of  $\text{Mg}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Me}^{2+}$  ( $\text{Co}^{2+}$ ,  $\text{Mn}^{2+}$  or  $\text{Ni}^{2+}$ ) and  $\text{Al}^{3+}$  (200 ml) was added slowly with vigorous stirring into an aqueous solution of sodium carbonate (400 ml). The pH of the solution was adjusted at 10.0 by dropping a 1 M aqueous solution of sodium hydroxide, leading to a precipitation of heavy slurry. After the solution was aged at 60 °C for 24 h, the solution was filtrated and the precipitates were washed with de-ionized water (1000 ml), dried in air at 100 °C for 4 h, and calcined at 550 °C for 12 h using a muffle furnace in a static air atmosphere. The concentration of  $\text{Na}^{2+}$  in the catalysts after the calcination was confirmed to be less than 10 ppm by atomic absorption.

### 3.2.2.2.Synthesis of mesoporous alumina doped with iron-oxide

Iron doped organized mesoporous alumina was synthesized using aluminium isopropoxide (98%, Aldrich). Alumina powders were synthesized using the neutral template approach as described by Yuan et al. [63]. The procedures were modified in order to accommodate the iron. In a typical synthesis, 1.0 g of Pluronic P123 ( $M_{av} = 5800$ ,  $EO_{20}PO_{70}EO_{20}$ ) was dissolved in 10.0 ml of ethanol at ambient temperature. Then 1.5 ml of 67 wt%  $HNO_3$  and 2.04 g of aluminium iso-propoxide were added after 2 h into the above solution with vigorous stirring. The mixture was covered with PE film and let stir at ambient temperature for 5 h. After solvent evaporation, which was carried out at 40 °C for 72 h, samples were calcined in standing air from 25 to 550 °C (1 °C/min ramping rate, 5 h hold time). Pure organized mesoporous alumina is noted as meso. $Al_2O_3$ .

Iron was added to organized mesoporous alumina via two different methods; direct (one-pot) synthesis and post synthesis. The direct synthesis procedures were similar to that of pure alumina powder except that the required amount of iron precursor (iron (III) nitrate hexahydrate, unless otherwise specified) that corresponds to Fe content of 21 wt% was dissolved with triblock copolymer template. Post synthesis was carried out using the conventional incipient (wetness) impregnation method. In a typical preparation, iron (III) nitrate hexahydrate was dissolved in distilled water. Subsequently, alumina powder was slowly added. The slurry was mixed at ambient temperature for 2 h, and then water was slowly evaporated while stirring. Samples were then dried at 120 °C overnight followed by calcinations treatment similar to that of pure alumina powder. Iron based samples obtained by direct and post synthesis are noted as xFe-meso. $Al_2O_3$ , and xFe/meso. $Al_2O_3$ , respectively (where x is 21 corresponding to Fe content in wt%).

### 3.2.3. Catalyst Characterization

A comprehensive catalyst characterization was done to determine the physico-chemical properties of the synthesized catalysts. The following characterization techniques were employed:

i. BET Surface Area and pore size distribution

The textural properties of synthesized samples were characterized by N<sub>2</sub> adsorption measurements at 77 K, using Quantachrome Autosorb 1-C adsorption analyzer. Samples were outgassed at 220 °C under vacuum ( $10^{-5}$  Torr) for 3 h before N<sub>2</sub> physisorption. The BET specific surface areas were determined from the adsorption data in the relative pressure ( $P/P_0$ ) range from 0.06-0.2, assuming a value of 0.164 nm<sup>2</sup> for the cross-section of the nitrogen molecule. The pore size distribution (PSD) was calculated from the adsorption branch using the Barrett-Joyner-Halenda (BJH) method.

ii. Atomic Absorption

The chemical compositions of synthesized HT quaternary mixed oxides of Mg/Fe/*Me*/Al (*Me* = Co, Mn, Ni) and Fe<sub>2</sub>O<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub> were determined by atomic absorption spectroscopy, using the Perkin-Elmer equipment (Model AAnalyst 100).

iii. X-ray Diffraction

XRD was recorded on a Mac Science MX18XHF-SRA powder diffractometer with monochromatized CuK $\alpha$  radiation ( $\lambda = 0.154$  nm) at 40 kV and 30 mA. The diffraction pattern was identified through comparison with those included in the

JCPDS (Joint Committee of Powder Diffraction Standards) database and literatures.

iv. X-ray Photoelectron Spectroscopy

XPS measurements were performed on a Perkin Elmer 1600E spectrometer using Mg K $\alpha$  radiation as excitation source. In charge-up correction, the calibration of binding energy (BE) of the spectra was referenced to the C 1s electron bond energy corresponding to graphitic carbon at 284.5 eV. In addition, relative atomic sensitivity factors (ASF) were corrected to determine practically more accurate chemical compositions on the surface.

v. Fourier Transform Infrared Spectroscopy

Infrared spectroscopy of adsorbed pyridine was used to determine the types of acid sites present on the alumina at different extents of Fe surface coverage. The measurements were carried out using a Fourier transform infrared Nicolet spectrometer (Magna 500 model).

vi. Temperature - Programmed Desorption

Temperature-programmed desorption of NH<sub>3</sub> (NH<sub>3</sub>-TPD) was carried out using Quantachrome Autosorb 1-C/TCD. Samples were pretreated at 300 °C in a flow of He (50 ml min<sup>-1</sup>) for 3 h. This was followed by the adsorption of ammonia (5 vol.% in He) at 100 °C for 30 min. Samples were then purged in a He stream for 2 h at 100 °C in order to remove loosely bound ammonia (i.e. physisorbed and H-bonded ammonia). Then, the samples were heated again from 100 to 550 °C at a heating rate of 10 °C/min in a flow of He (25 ml/min) while monitoring the evolved ammonia using TCD.

### **3.3. GC calibration**

The calibration of the gas chromatograph used in determining the product composition of the ethylbenzene dehydrogenation reaction was done as explained in sections 3.3.1 and 3.3.2 below:

#### **3.3.1. Determination of retention time for the different compounds**

The retention times of all compounds of interest in this work were determined by analyzing pure samples of each of the compounds in the GC in turns. Table A3.1 (Appendix) shows the different compounds and their corresponding retention times. These retention times were used to identify each component of the reaction products.

#### **3.3.2. Correlating GC response and actual weight percentage of each compound**

In calibrating the GC, standard samples of different compositions containing ethylbenzene and the main reaction products (styrene, benzene, toluene) were prepared. The composition of the prepared samples were carefully chosen to reflect all the possible product compositions (obtained from preliminary experimental runs) under the different reaction conditions to be investigated. 0.2 $\mu$ l of the first sample was then injected into the GC and the GC responses (area %) for each of the components in sample were obtained. The sample procedure was repeated for all the other samples.

### **3.4. Catalyst Evaluation**

Ethylbenzene dehydrogenation was carried out over the synthesized hydrotalcite and Fe<sub>2</sub>O<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts in order to test their catalytic activity. The HT catalysts were evaluated for the dehydrogenation process at reaction temperatures of 400, 450, 500 and 550 °C while Fe<sub>2</sub>O<sub>3</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts are tested at reaction temperatures of 350, 400, 450,

500 and 550 °C. For each reaction temperature, all catalysts were tested for reaction times of 5, 10, 15 and 20 sec. To enhance the reproducibility of the data, experimental runs for each reaction condition was repeated at least twice.

#### **3.4.1. Testing Procedure**

In a typical experiment, the reactor was charged with 0.8g of catalyst previously crushed and sieved to a particle size of ~ 60 µm diameter. The catalyst/reactant ratio was 5 (weight of catalyst = 0.81 g, weight of reactant injected = 0.162 g). The system is then sealed and tested for any pressure leaks by monitoring the pressure changes in the system. Furthermore, the reactor is heated to the desired reaction temperature. The vacuum box is also heated to around 250°C and evacuated to around 0.5 psi to prevent any condensation of hydrocarbons inside the box. The heating of the riser simulator is conducted under continuous flow of inert gases (argon) and the process usually takes few hours until thermal equilibrium is finally attained. Meanwhile, before the initial experimental run, the catalyst is activated for 15 minutes at 620°C with air. The temperature controller is set to the desired reaction temperature likewise the timer is set to the desired reaction time. At this point the GC is started and set to the desired conditions.

Once the reactor and the gas chromatograph have reached their desired operating conditions, 200µl of the feed stock is injected directly into the reactor via a loaded syringe while the impeller is rotating at a speed of 6000rpm. After the reaction, the four port valve opens immediately ensuring that the reaction is terminated and the entire product stream sent online to the gas chromatograph via the pre-heated vacuum box chamber. The products are then analyzed in the gas chromatograph .After each

experimental run, the catalyst is regenerated at conditions similar to initial activation.

The ethylbenzene (EB) conversion is expressed as follows:

$$X_{EB} = \frac{\text{moles of converted ethylbenzene}}{\text{moles of ethylbenzene fed}} \times 100$$

The selectivity (to product i) is expressed as follows:

$$S_i = \frac{\text{Number of carbon atoms of product i}}{\text{Number of carbon atoms of converted products}} \times 100$$

The yield (to product i) is expressed as follows:

$$Y_i = \frac{S_i}{X_{EB}} \times 100$$

### 3.5. Coke Analysis

The amount of coke deposited on the spent catalysts was determined by the combustion principle of the carbon analyzer multi EA 2000 (Analytikjena). A small amount of the spent catalyst (0.09 – 0.1g) is weighed into the combustion boat and fed completely into the hot zone of the furnace. Oxygen is fed directly into the unit and the coke deposit on the spent catalyst is burned completely, converting the carbonaceous deposit into carbon dioxide. The amount of coke formed is determined by measuring the number of moles of CO<sub>2</sub> released. This technique however cannot be used to determine the nature of the coke formed.

## CHAPTER 4

### 4.0 RESULTS AND DISCUSSIONS

#### 4.1 Ethylbenzene dehydrogenation over HT precursors of $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$ ( $\text{Me} = \text{Co}, \text{Mn}$ and $\text{Ni}$ ) catalysts.

##### 4.1.1. Physico-chemical properties

##### 4.1.1.1. Chemical composition and textural properties

The textural properties along with metal composition of  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}$  and  $\text{Ni}$ ) catalysts after the calcination at 550 °C are shown in Table 4.1. It can be clearly seen from Table 4.1 that all  $\text{Mg}_3\text{Fe}_{0.5}\text{Me}_{0.5}\text{Al}_{0.5}$  catalysts exhibit large  $S_{\text{BET}}$  between 150 and 200  $\text{m}^2 \text{g}_{\text{cat}}^{-1}$ . This can be mainly attributed to the ability of Mg–Al and Mg–Fe to form the hydrotalcite structure, resulting in large surface area after the calcination. The relatively low  $S_{\text{BET}}$  (158  $\text{m}^2\text{g}^{-1}$ ) of  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$  compared to other catalysts is probably due to plugging of the pores with segregated bulk manganese oxide particles. This was suggested by XRD and  $\text{H}_2$ -TPR, which are discussed in the following paragraphs. It is also worth mentioning that the metal compositions are in complete agreement with the nominal values. This is due to the formation of hydrotalcite structure as the precursors during the coprecipitation, which accommodates many metal cations in the structure. Furthermore, the average pore diameter of hydrotalcites based samples is in the mesopore region (2-50 nm), as suggested by the pore size distributions (Figure 4.1A-C).

**Table 4.1**Specific surface area, metal composition, and XPS analytical data of  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$ *(Me = Co, Mn and Ni)*

Catalyst	$S_{\text{BET}}/\text{m}^2\text{g}_{\text{cat}}^{-1}$	Molar ratio <sup>a</sup>			Binding energy <sup>b</sup> /eV			Surface molar ratio <sup>b,c</sup>	
		Mg/Fe	Mg/Al	Mg/Me	Mg 2p <sub>3/2</sub>	Fe 2p <sub>3/2</sub>	Me 2p <sub>3/2</sub>	Mg/Fe	Mg/Me
$\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$	187	11.5	5.5	11.5	48.9	710.6	779.6	6.5	5.0

Figure 4.1. Pore size distribution of  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$ , where  $\text{Me} = \text{Co}$  (A),  $\text{Mn}$  (B), and  $\text{Ni}$  (C)

#### 4.1.1.2. Surface analysis of the catalysts

The XPS analytical results of  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}$  and  $\text{Ni}$ ) after calcination at  $550^\circ\text{C}$  are summarized in Table 4.1. The surface molar ratios of  $\text{Mg}/\text{Fe}$  and  $\text{Mg}/\text{Me}$  calculated from the XPS results exhibited lower values than the bulk molar ratios obtained by AA analyses (Table 4.1). This indicates that both Fe and second component metal ( $\text{Me}$ ) species are localized in the surface layer of the catalyst particles. On all  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  catalysts except  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$ , Fe species showed similar surface enriched localization, i.e., almost 1.4 times higher concentration in the surface layer than the bulk phase. Surface enrichment of Fe was not so significant for  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$ . Contrarily, some of the second component metals exhibited far enriched distribution in the surface layer, i.e., the highest concentration in the surface layer was obtained by Ni (5 times), followed by Co (2.2 times) and Mn (1.3 times). The scattered experimental values for Mn clearly suggest that Mn dispersion on the catalyst was not homogeneous.

#### 4.1.1.3. Bulk phase identification

XRD patterns of  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}$  and  $\text{Ni}$ ) catalysts after drying are shown in Figure 4.2a. It can be noted that all  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  showed typical hydrotalcite reflections, indicating that the second metal components were incorporated into the hydrotalcite structure except  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ .  $\text{Mn}^{2+}$  possesses a larger ionic radii of  $0.80 \text{ \AA}$  than the other  $\text{Me}^{2+}$  [73] and requires the highest pH for its complete precipitation as hydroxides among the  $\text{Me}$  cations used [40]. After the calcination at  $550^\circ\text{C}$  (Figure 4.2b), all samples showed the periclase reflections together with weak spinel reflections. This indicates that iron was incorporated in the periclase and the spinel.

Figure 4.2. XRD patterns of  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}$  (a),  $\text{Mn}$  (b) and  $\text{Ni}$  (c)) after A) drying and B) calcination at  $550\text{ }^\circ\text{C}$  (■: Hydrotalcites; ◆: unknown and ▼: periclase)

#### 4.1.1.4. Reducibility of the active specie on the catalysts

H<sub>2</sub>-TPR data of Mg<sub>3</sub>Fe<sub>0.25</sub>Me<sub>0.25</sub>Al<sub>0.5</sub> (Me = Mn, Ni, and Co) are shown in Figure 4.3. Mg<sub>3</sub>Fe<sub>1</sub> showed a reduction peak at 418 °C and a broad peak above 650 °C (Figure 4.3a). The first peak is attributed to the reduction of spinel (MgFe<sup>3+</sup><sub>2</sub>O<sub>4</sub>) to periclase (Mg<sub>1-x</sub>Fe<sup>2+</sup><sub>x</sub>O) and the latter is to the reduction of Mg<sub>1-x</sub>Fe<sup>2+</sup><sub>x</sub>O to Fe<sup>0</sup>, as reported by Shen et al. [74], Mg<sub>3</sub>Fe<sub>0.25</sub>Ni<sub>0.25</sub>Al<sub>0.5</sub> showed a weak reduction peak at 353 °C and broad reduction peak above 800 °C. The latter is attributed to the reduction of Ni<sup>2+</sup> in the Mg(Ni)O periclase [75]. Therefore, the one observed at 353 °C can be attributed the reduction of Fe<sup>3+</sup> species. Mg<sub>3</sub>Fe<sub>0.25</sub>Mn<sub>0.25</sub>Al<sub>0.5</sub> exhibited rather strong two reduction peaks at 257 °C and 428 °C (Figure 4.3c). This catalyst exhibited unknown reflections together with those of hydrotalcite after drying (Figure 4.2b), suggesting that manganese oxides were separated from periclase after calcination. It was reported that a mixed oxide of Mg<sub>0.2</sub>Mn<sub>1.8</sub>Al<sub>1</sub> composition derived from hydrotalcite and calcined at 500 °C showed two reduction peaks at 333 °C and 460 °C [76]. This also suggests that manganese oxides were separated from periclase structure in Mg<sub>3</sub>Fe<sub>0.25</sub>Mn<sub>0.25</sub>Al<sub>0.5</sub> and showed the reduction peaks at 257 °C and 428 °C.

Figure 4.3. H<sub>2</sub>-TPR of Mg<sub>3</sub>Fe<sub>0.25</sub>Me<sub>0.25</sub>Al<sub>0.5</sub> (*Me* = Co, Mn, and Ni) catalysts. a) Mg<sub>3</sub>Fe<sub>1</sub>; b) Mg<sub>3</sub>Fe<sub>0.5</sub>Al<sub>0.5</sub>; c) Mg<sub>3</sub>Fe<sub>0.25</sub>Mn<sub>0.25</sub>Al<sub>0.5</sub>; d) Mg<sub>3</sub>Fe<sub>0.25</sub>Co<sub>0.25</sub>Al<sub>0.5</sub>; and f) Mg<sub>3</sub>Fe<sub>0.25</sub>Ni<sub>0.25</sub>Al<sub>0.5</sub>.

#### 4.1.2. Catalytic Activity

The product distribution of the ethylbenzene dehydrogenation reaction over  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}$  and  $\text{Ni}$ ) catalysts at different reaction temperatures and reaction times are presented in Tables 4.2–4.4. The experimental results showed styrene to be the main reaction product, although small amounts of benzene were obtained as by product. Traces of toluene, gaseous hydrocarbons, diethylbenzene (DEB) were also observed; however the yields of these products were neglected in subsequent analysis. In all the catalysts investigated, EB conversion increased with both reaction temperature and time and maximum conversion of approximately 15.5, 19.7, 18.0% was attained at 20 s of time on stream and temperature of 550 °C for  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ ,  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ , and  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$  catalysts respectively as shown in Figure 4.4(A-C). The mixed oxides catalyst consisting of  $\text{Mn}^{2+}$  gave the highest activity regardless of its low surface area. This may be accounted for by the isolation of manganese oxides from the periclase structure, as suggested by XRD, XPS and  $\text{H}_2$ -TPR. Therefore, the inhomogeneous dispersion of  $\text{Mn}^{2+}$  on the catalyst (i.e. presence of segregated (bulk) Mn oxide) is assumed to increase the active sites of the catalyst. One may suggest that the segregated manganese oxide further contributes to the basicity of MgO which has been reported to initiate  $\text{H}^+$  abstraction [48]. The investigation of iron oxide catalysts containing various transition metal oxides by Hirano [77] also showed that increase in basicity due to reduction in electronegativity of the promoter gave rise to the dehydrogenation activity of the catalyst. As a control, a commercial catalyst was also tested. It showed a low activity as shown in Figure 4.5 which can be attributed to the absence of steam.

**Table 4.2**

Figure 4.4. Conversion of ethylbenzene with respect to time at various temperatures over different hydrotalcite mixed oxides; A)  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ , B)  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ , and C)  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$ .

Figure 4.5. Conversion of ethylbenzene with respect to time at 500 °C, comparison between commercial and HT catalysts

#### 4.1.2.1. Styrene/Benzene Selectivity

The product selectivity during the dehydrogenation of EB over  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}$  and  $\text{Ni}$ ) and commercial catalysts were compared in Figure 4.6 at constant conversion level of  $\sim 6\%$ . The results show that styrene is obtained as the most predominant product on all the HT catalysts with the best selectivity observed in  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ . The selectivity towards styrene exhibits a trend opposite to EB conversion for all the HT catalysts investigated. It decreased when the reaction temperature was raised due to cracking reaction. Figure 4.7 shows selectivity as a function of the EB conversion for all the reaction temperatures for  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ , showing a maximum styrene selectivity of 92.7% at reaction temperature of 400 °C which corresponds to 4.9% EB conversion. However, benzene selectivity increased as the temperature was raised. This confirmed that cracking of EB to benzene becomes pronounced at high temperature as shown in Figure 4.7. A maximum benzene selectivity of 25.1% was attained at 550 °C corresponding to 19.7% EB conversion. On the contrary, the commercial catalyst has low selectivity towards styrene which was due to significant cracking and such an occurrence has been suggested by Lee [14] to be as a result of increase in acidity of the catalyst due to loss of potassium from the catalyst surface.

It is also worth mentioning that  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$  catalyst exhibited much lower selectivity to diethylbenzene (DEB, three isomers) than the other two catalysts ( $\text{Co}^{2+}$  and  $\text{Ni}^{2+}$ ). Therefore, it can be inferred from these results that  $\text{Mn}^{2+}$  does not favor the disproportionation reaction. For instance, the selectivity to DEB (temperature = 400 °C and residence time = 20s) over  $\text{Mn}^{2+}$ ,  $\text{Co}^{2+}$ , and  $\text{Ni}^{2+}$  based oxides were 1.0 wt%, 6.9 wt% and 7.6 wt%, respectively (Tables 4.2-4.4).

Figure 4.6. Product selectivity of ethylbenzene dehydrogenation over the different catalysts at ~ 6% ethylbenzene conversion

Figure 4.7. Selectivity with respect to conversion and temperature for  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$

#### 4.1.2.2. Styrene/Benzene Yield

The yield of styrene was found to increase with both temperature and time, in a similar manner with EB conversion. Maximum styrene yield of approximately 8.8, 12.3, and 11.2% for  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ ,  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$  and  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$  catalysts respectively were attained at reaction temperature of 550 °C and 20 s time on stream.  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$  gave the maximum styrene yield, and its variation with temperature is shown in Figure 4.8A. Similarly, benzene yield was equally increasing with both temperature and time with a maximum of approximately 4.6, 4.9, and 4.3% for  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ ,  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ , and  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$  catalysts respectively at 550 °C for reaction time of 20 s. Figure 4.8B shows the variation of benzene yield with temperature for  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ . It can thus be concluded that for longer reaction time, EB undergoes both dehydrogenation and dealkylation reactions to give styrene and benzene respectively. It can also be seen from Tables 4.2-4.4 that both the yield of DEB (disproportionation product) and toluene (cracking product) increased with temperature.

Figure 4.8. Styrene (A) and benzene (B) yields vs. ethylbenzene conversion at various temperatures for  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$

#### **4.1.3. Coke Content Measurement**

Table 4.5 shows the amount of coke deposited for the catalysts investigated at 550 °C. The data revealed low coke yield, and the ratio of coke weight percent to percent conversion is small. Similarly, coking on the commercial catalyst was low. This implies that dehydrogenation of ethylbenzene over the catalysts is not accompanied by substantial coke deposition. It can thus be inferred that loss of activity of this commercial catalyst in the absence of steam was not due to coking but as a result of solid state transformation, though the exact deactivation mechanism was not studied.

**Table 4.5**

Coke formation of Ethylbenzene dehydrogenation reaction at different reaction conditions

Catalysts	Temp (°C)	Reaction time (s)	Conversion (%)	Coke wt (% C)	Coke wt/ conversion
$\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$	550	10	11.38	0.503	0.044
		20	15.46	0.488	0.032
$\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$	550	10	15.02	0.618	0.041
		20	19.70	0.694	0.035

		20	11.15	0.446	0.040

#### 4.1.4. Kinetic Modeling

##### 4.1.4.1. Model development

In addition to the main dehydrogenation reaction (equation 4.1), the side reactions (equations (4.2) – (4.4)) are also known to take place

A reaction scheme for EB dehydrogenation is given as scheme 1, neglecting the disproportionation reaction based on the product distribution. Adapting this scheme to the model development in estimating the kinetic parameters, toluene formation was not considered owing to its very low concentration in the reaction product.

scheme 1

Scheme 1 Catalytic reaction scheme of ethylbenzene (EB) dehydrogenation

The experimental results were modeled using catalyst deactivation function model based on both reactant conversion (RC) and time-on-stream (TOS) catalyst decay function.

#### 4.1.4.2. Catalyst activity decay function based on reactant conversion (RC)

This type of catalyst deactivation function model was developed by Al-Khattaf and de Lasa [78]. According to this model, the deactivation is based on the conversion of ethylbenzene which is directly related to coke formation. This approach is more sound than time-on-stream approach which has been widely used in literature to account for catalyst deactivation. From the reaction network shown in scheme and the assumption that toluene formation is neglected, the following set of species balances and catalytic reactions can be written:

Rate of EB disappearance,  $r_{EB}$

$$-\frac{V}{W_c} \frac{dC_{EB}}{dt} = (k_1 C_{EB} - k_{-1} C_{ST} C_H + k_2 C_{EB}) \varphi \quad (4.5)$$

Rate of styrene appearance,  $r_{ST}$

$$\frac{V}{W_c} \frac{dC_{ST}}{dt} = (k_1 C_{EB} - k_{-1} C_{ST} C_H) \varphi \quad (4.6)$$

Rate of formation of benzene,  $r_B$

$$\frac{V}{W_c} \frac{dC_B}{dt} = k_2 C_{EB} \varphi \quad (4.7)$$

where  $C_i$  is molar concentration of each of the species in the riser simulator,  $V$  is the volume of the riser (45 cm<sup>3</sup>),  $W_c$  is the mass of the catalyst (0.81 g-cat),  $t$  is time (in seconds),  $k$  is the rate constant (cm<sup>3</sup>/(g-cat·s)), and  $\varphi$ , the catalyst decay function, which accounts for the loss of catalytic activity as a result of deactivation due to coking. For the reactant conversion model, the catalyst deactivation function is given as:

$$\varphi = \exp(-\lambda(1 - y_{EB})) \quad (4.8)$$

where  $\lambda$  is catalyst deactivation constant

By definition, the molar concentration  $C_i$  of each species can be written in terms of its mass fraction  $y_i$ , which are the measurable variables from our chromatographic analysis, by the following relation:

$$C_i = \frac{y_i W_{hc}}{MW_i V} \quad (4.9)$$

where  $W_{hc}$  is the weight of feedstock injected into the reactor,  $MW_i$  is the molecular weights of the individual species and  $V$  is the volume of the riser simulator.

To ensure thermodynamic consistency at equilibrium, the temperature dependent equilibrium constant for the reversible reaction was found to be:

$$K_c = \frac{k_1}{k_{-1}} \quad (4.10)$$

which has been calculated from literature as [32]:

$$K_C = \exp \left\{ - \left( \frac{122700 - 126.3T - 2.194 \times 10^{-3}T^2}{RT} \right) \right\} \times 10^5 \text{ Pa} \quad (4.11)$$

Substituting Eq. (4–6) into Eqs (1–3) and simplifying gives the following:

$$\frac{dy_{EB}}{dt} = - \left[ k_1 \left( y_{EB} - G_1 \frac{y_{ST}y_H}{K_C} \right) + k_2 y_{EB} \right] \frac{W_C}{V} \exp(-\lambda(1 - y_{EB})) \quad (4.12)$$

$$\frac{dy_{ST}}{dt} = k_1 \left( G_2 y_{EB} - G_3 \frac{y_{ST}y_H}{K_C} \right) \frac{W_C}{V} \exp(-\lambda(1 - y_{EB})) \quad (4.13)$$

$$\frac{dy_B}{dt} = G_4 k_2 y_{EB} \frac{W_C}{V} \exp(-\lambda(1 - y_{EB})) \quad (4.14)$$

$G_1$ ,  $G_2$ ,  $G_3$ , and  $G_4$  are lumped constants given as:

$$G_1 = \frac{MW_{EB}W_{hc}}{MW_{ST}MW_HV}$$

$$G_2 = \frac{MW_{ST}}{MW_{EB}}$$

$$G_3 = \frac{W_{hc}}{MW_HV}$$

$$G_4 = \frac{MW_B}{MW_{EB}}$$

The activation energy,  $E_i$ , for the dehydrogenation reaction is related to temperature dependent rate constants  $k_i$  according to the Arrhenius equation given below:

$$k_i = A_i \exp \left( - \frac{E_i}{RT} \right) \quad (4.15)$$

where  $A_i$  is called the pre-exponential factor. Agarwal and Brisk have suggested re-parameterization of equation above during kinetic modeling to help reduce parameter interaction. Therefore,  $k_i$  constants were re-parameterized by centering the values around  $k_{0i}$  which is the value of the rate constant for reaction  $i$  at the average temperature  $T_0$  of the investigated temperatures [79]:

$$k_i = k_{0i} \exp \left[ -\frac{E_i}{R} \left( \frac{1}{T} - \frac{1}{T_0} \right) \right] \quad (4.16)$$

Since the experimental runs were done at 400, 450, 500 and 550 °C,  $T_o$  was calculated to be 475 °C.

The above reaction model equations were derived based on the following assumptions:

1. Catalyst deactivation was assumed to be a function of reactant conversion. And, a single deactivation function was defined for all the reactions.
2. The model assumes only catalytic reactions and neglects thermal conversion.
3. The reactor operates under isothermal conditions, justified by the negligible temperature change observed during the reaction.
4. Toluene yield is negligible.
5. The model also neglects the disproportionation reaction.

#### 4.1.4.3. Catalyst activity decay function based on time-on-stream (TOS)

The catalyst activity decay model based on time-on-stream was initially suggested by Voorhies [80]. Since then, this model has been used extensively throughout the FCC literature. This model is empirically based given it does not incorporate a mechanistic description of catalyst deactivation. As a result, extrapolations of activity decay with this model are quite uncertain.

Modeling of the catalytic reactions based on TOS follows the same procedure as RC. In this case catalyst deactivation due to coke formation is related to time. Carbon deposit on catalyst increases with time, therefore the catalyst deactivation function is given as:

$$\varphi = \exp(-\alpha t) \quad (4.17)$$

The model equations obtained based on similar assumptions for RC are thus:

$$\frac{dy_{EB}}{dt} = - \left[ k_1 \left( y_{EB} - G_1 \frac{y_{ST} y_H}{K_C} \right) + k_2 y_{EB} \right] \frac{W_c}{V} \exp(-\alpha t) \quad (4.18)$$

$$\frac{dy_{ST}}{dt} = k_1 \left( G_2 y_{EB} - G_3 \frac{y_{ST} y_H}{K_C} \right) \frac{W_c}{V} \exp(-\alpha t) \quad (4.19)$$

$$\frac{dy_B}{dt} = G_4 k_2 y_{EB} \frac{W_c}{V} \exp(-\alpha t) \quad (4.20)$$

where  $G_1$ ,  $G_2$ ,  $G_3$ , and  $G_4$  are lumped constants already defined.

#### 4.1.4.4. Determination of model parameters

##### A. Reactant Conversion Model

The kinetic parameters  $k_{oi}$ ,  $E_i$  and  $\lambda$  for the reactions were determined by fitting experimental results into the rate equations 4.12–4.14 using non-linear regression analysis with the aid of MATLAB package. The values of the model parameters along with their corresponding 95% confidence limits (CLs) are shown in Table 4.6 while the resulting cross-correlation matrices are also given in Table 4.7 for  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ ,  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$  and  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$  catalysts respectively. As shown in Table 4.7 the correlations between  $k_1$  and  $E_1$ ,  $E_1$  and  $\lambda$  and  $k_1$  and  $\lambda$  for all the estimated parameters of dehydrogenation reaction to produce styrene with correlations between  $k_2$  and  $E_2$ ,  $E_2$  and  $\lambda$  and  $k_2$  and  $\lambda$  of cracking reaction have low and moderate level of parameter interaction with only a few exceptions. From the results of the kinetic parameters, the estimated apparent energies for dehydrogenation of EB to St. for  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ ,  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ , and  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$  catalysts are 18.3, 15.6, and 20.9 kcal/mol respectively. These values are found to be lower compared to those reported in most literatures; however, the result obtained for  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$  is essentially the same as that reported by Addiego et al. [36], an apparent activation energy of 21 kcal/mol for 30% K-promoted  $\text{Fe}_2\text{O}_3$ . The activation energies estimated for dealkylation reactions which are 22.3, 26.7, and 22.7 kcal/mole for  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ ,  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$ , and  $\text{Mg}_3\text{Fe}_{0.25}\text{Ni}_{0.25}\text{Al}_{0.5}$  catalysts respectively, are found to be higher than that for dehydrogenation reaction. Similar trend has been reported by Hirano [18,19] both for unpromoted and promoted iron oxide catalysts. This indicates that high activation energy must be overcome for the cracking reaction to proceed.

## B. Time-on-stream Model

Using the experimental data for the EB dehydrogenation, the model parameters  $k_{oi}$ ,  $E_i$  and  $\alpha$  of equations 4.18–4.20 were estimated using non-linear regression in a similar manner as that of the RC model. Table 4.8 reports the values of the parameters obtained and the 95% confidence interval. Table 4.9 shows the correlation matrix indicating low to moderate parameter interaction.  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$  gave the best activity and selectivity based on the estimated parameters which is in accordance with the conclusion reached with RC model.

From the estimated activation energies, the addition of  $\text{Mn}^{2+}$  to ternary  $\text{Mg/Fe/Al}$  HT best improved its catalyst activity even though both  $\text{Co}^{2+}$  and  $\text{Ni}^{2+}$  are well incorporated into the HT structure.  $\text{Mg}_3\text{Fe}_{0.25}\text{Mn}_{0.25}\text{Al}_{0.5}$  has the least activation energy to produce styrene and highest energy to be overcome to crack EB to yield Bz. This further depicts that  $\text{Mn}^{2+}$  gave the best selectivity towards styrene formation which is consistent with the experimental data. This assertion can be justified from the results of the characterization of the catalysts.  $\text{Mn}^{2+}$  has been reported to possess a higher ionic radius than the other  $\text{Me}^{2+}$  which may have led to its incomplete incorporation into the HT structure [47]. The result of XPS from Table 4.1 shows  $\text{Mn}^{2+}$  to have the least binding energy. Binding energy has been reported to be linked to the strength of basicity of a catalyst [81], the lower the binding energy, the more basic the surface of the catalyst. It can thus be suggested that the segregation of  $\text{Mn}^{2+}$  serves as additional active sites which increased the basicity of the catalyst, responsible for initiating dehydrogenation by  $\text{H}^+$  abstraction [48]. The active specie however is still identified as the metastable  $\text{Fe}^{3+}$ .

The use of fluidized bed reactor is suggested to have improved the overall performance of this process. This same experiment (EB dehydrogenation) was conducted using a continuous gas-flow fixed bed reactor at atmospheric pressure [47] over  $\text{Mg}_3\text{Fe}_{0.25}\text{Co}_{0.25}\text{Al}_{0.5}$ . The reaction was carried out for 3 h of time-on-stream at 550 °C with the catalyst after been pre-treated with a He gas. Activation energy of 29.1 kcal/mol was estimated from the Arrhenius plot. It can thus be assumed that the extensive bed mixing and heat distribution within the fluidized bed enhanced reactant-catalyst contact and uniform product quality, hence reduction of activation energy towards styrene formation.

In order to ascertain the proposed models developed for the dehydrogenation process of EB in the riser simulator, validation of the estimated kinetic parameters is imperative. Therefore, the estimated parameters were substituted into the set of differential equations developed and solved numerically using fourth-order-Runge-Kutta routine. The numerical results were compared with experimental data as shown in Figure 4.4(A-C). As observed from the Figure, the model predictions compared favorably with the obtained experimental data. This demonstrates that the proposed kinetic model fits well into our experimental observations. To further determine the adequacy of the model, a reconciliation plot (Figure 4.9) showing the overall agreement of experimental data and model predictions was done. The two agrees very well as suggested by the value of regression coefficient,  $r^2$  (0.99).

## **4.2 Ethylbenzene dehydrogenation over $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$**

### **4.2.1. Catalyst characterization**

#### **4.2.1.1 $\text{N}_2$ adsorption-desorption isotherm**

The  $\text{N}_2$  adsorption-desorption isotherm for all the  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  samples calcined at 550 °C is shown in Fig 4.10. All samples show typical type IV isotherms with H1 hysteresis loops characteristic of mesoporous materials suggesting their uniform cylindrical pores [82]. The condensation step observed over mesoporous alumina doped with iron is steeper and greater compared to the conventional alumina support for iron. This indicates uniformity of mesopores having a large pore volume as seen in Table 4.10. All samples possessed mesoporosity and high specific surface area, as inferred from nitrogen isotherms.

Figure 4.10. N<sub>2</sub> adsorption-desorption isotherm

Average Pore Diameter (nm)	5.80	11.0

#### 4.2.1.2 X-ray Diffraction patterns

XRD patterns of mesoporous alumina, obtained by self-induced evaporation methods reveal no evidence of crystalline alumina phase. Yuan et al. has attributed this occurrence to the presence of  $\gamma$ - $\text{Al}_2\text{O}_3$  which only crystallizes at higher calcinations temperature ( $> 700^\circ\text{C}$ ) while peaks which are attributed to the presence of crystalline alumina phase were observed on the pure conventional  $\text{Al}_2\text{O}_3$ . When loaded with 21%Fe by both direct and post synthesis methods, the XRD patterns were similar to that of the pure alumina support, however indistinctive reflections were noticed on iron doped on alumina by post synthesis method. This depicts that the metal specie were homogeneously distributed over mesoporous alumina support irrespective of the preparation method. XRD analysis of the conventional  $\text{Al}_2\text{O}_3$  doped with 21%Fe indicates the presence of bulk  $\text{Fe}_2\text{O}_3$  phase. The sample exhibits well defined reflections which are assigned to  $\text{Fe}_2\text{O}_3$ .

Figure 4.11b. XRD pattern of 21%Fe doped on alumina support

#### **4.2.1.3 Transmission Electron Microscopy (TEM)**

The TEM image of iron supported on mesoporous alumina reveals alternate white and dark patches which confirm the presence of high fraction of highly dispersed active iron surface species which has also been suggested from the results of the XRD. The three white diagonal lines show the particle size distance approximately to be 9 nm. This value is close to the pore diameter estimated from the N<sub>2</sub> adsorption isotherm. This further confirms the periodic ordering of the catalyst resulting from self assembly by the pore directing agent. In addition to the high degree of order, the supported Fe on mesoporous alumina possessed large and uniform mesopores as well as high specific surface area as obtained from nitrogen adsorption isotherm. The selective area electron diffraction (SAED) pattern (insert in Figures 4.12a & 4.12b) of the ordered mesostructure domains indicates the presence of crystalline Fe<sub>2</sub>O<sub>3</sub> phase. Additional proof of the crystallinity of this specie is given by high resolution TEM image (Figure 4.12b) which reveals the existence of crystalline nanoparticles of Fe<sub>2</sub>O<sub>3</sub>. Bulk Fe<sub>2</sub>O<sub>3</sub> phase obtained from XRD analysis of Fe supported on conventional was also confirmed by the TEM image shown in Figure 4.12b.

#### 4.2.2. Catalyst Activity

All the catalysts examined enhanced the formation of styrene which was the major product of the reaction whereas benzene was a minor by-product. Toluene and gaseous hydrocarbons were observed in trace amounts. The catalytic activities of all the catalysts at different reaction conditions are shown in Tables 4.11 – 4.13. 21%Fe-org. $\text{Al}_2\text{O}_3$  (one-pot) catalyst gave the highest activity with a maximum conversion of ~22.9 % at 550 °C for a reaction time of 20 s. However, it has a maximum yield of 18.3% towards styrene at 450 °C for a reaction time of 20 s at temperatures above 450 °C, the yield of styrene decreases with increase in benzene yield. This similar trend was observed in other catalysts as depicted in Figure 4.13. Though for the iron supported on conventional alumina catalyst, at 550 °C the yield was slightly higher than 450 °C, selectivity towards styrene was better at 450 °C. Thus, it can be concluded that for all the catalysts investigated a temperature of 450 °C appears to be an optimum for maximizing the yield of styrene. From Figure 4.13, it is evident that irrespective of the method employed in preparing the iron supported on organized alumina, a better styrene yield was obtained as compared to the conventional alumina doped with iron. This was mainly attributed to the presence of high fraction of highly dispersed active iron surface species as suggested by XRD patterns, TEM and XPS measurements.

Figure 4.13. Comparison of styrene yield for all reaction temperatures over  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$

The effect of reaction time and temperature on EB conversion over all the catalysts is shown in Figure 4.14(A – C). It is evident from the Figures that EB conversion increases with both reaction temperature and time. Table 4.14 summarizes the effect of reaction temperature on the catalytic properties of all the catalysts. The dehydrogenation activity increases significantly with the increase of temperature, but the styrene selectivity decreased. The amount of benzene in the reaction product is increased, showing that cracking reaction is favored at higher temperature. Under similar reaction conditions, iron-oxide doped on organized alumina catalysts seem even more active for EB dehydrogenation than the  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}, \text{Ni}$ ) hydrotalcite catalysts reported earlier.

### 4.2.3. Kinetic Modeling

#### 4.2.3.1. Model development

In addition to the main dehydrogenation reaction (equation 4.21), the side reactions (equations (4.22) – (4.23)) are also known to take place

A reaction scheme for EB dehydrogenation is given as scheme 1. To develop a suitable kinetic model based on the product distribution, two mechanisms are postulated to represent the disappearance of EB: one mechanism for low temperature range (350 – 450 °C), and another for the complete temperature range. Scheme 2 was adapted for the low temperature range whereby formation of both toluene and benzene were negligible while overall temperature range adopts scheme 3 in which formation of benzene is considered significant, however toluene is still negligible. Reaction schemes 2 and 3 will be employed to obtain the kinetic parameters of scheme 1.

scheme 1

Scheme 1 Catalytic reaction scheme of ethylbenzene (EB) dehydrogenation

scheme 2

scheme 3

(a) **Scheme 2: Low Temperatures.** At low temperatures (350 – 450 °C), the experimental results were modeled using steady-state approximations and considering catalyst decay to be a function of reactant conversion (RC). The following catalytic reactions were utilized:

Rate of disappearance of ethylbenzene,  $r_{EB}$

$$-\frac{V}{W_c} \frac{dC_{EB}}{dt} = (k_1 C_{EB} - k_{-1} C_{ST} C_H) \exp(-\lambda(1 - y_{EB})) \quad (4.24)$$

Rate of formation of styrene,  $r_{ST}$

$$\frac{V}{W_c} \frac{dC_{ST}}{dt} = (k_1 C_{EB} - k_{-1} C_{ST} C_H) \exp(-\lambda(1 - y_{EB})) \quad (4.25)$$

**(b) Scheme 3: Low and High Temperatures.** This is a comprehensive model covering the complete temperature considered in the study (i.e., 350 – 550 °C). This was also modeled using the steady-state approximations and considering catalyst decay to be function of RC. This scheme takes into account cracking of ethylbenzene to benzene, however from the product distribution, toluene is negligible. Thus, the following set of species balances and catalytic reactions were utilized:

Rate of disappearance of ethylbenzene,  $r_{EB}$

$$-\frac{V}{W_c} \frac{dC_{EB}}{dt} = (k_1 C_{EB} - k_{-1} C_{ST} C_H + k_2 C_{EB}) \exp(-\lambda(1 - y_{EB})) \quad (4.26)$$

Rate of formation of styrene,  $r_{ST}$

$$\frac{V}{W_c} \frac{dC_{ST}}{dt} = (k_1 C_{EB} - k_{-1} C_{ST} C_H) \exp(-\lambda(1 - y_{EB})) \quad (4.25)$$

Rate of formation of benzene,  $r_B$

$$\frac{V}{W_c} \frac{dC_B}{dt} = k_2 C_{EB} \exp(-\lambda(1 - y_{EB})) \quad (4.27)$$

where  $C_{EB}$  is the concentration of ethylbenzene,  $C_{ST}$  is the concentration of styrene,  $C_H$  is the concentration of hydrogen,  $C_B$  is the concentration of benzene in the riser simulator,  $V$  is the volume of the riser (45 cm<sup>3</sup>),  $W_c$  is the mass of the catalyst (0.81 g-cat),  $t$ , the time (in seconds),  $\lambda$ , the deactivation constant, and  $k$  is the rate constant (cm<sup>3</sup>/(g-cat·s)). The measurable variables from our chromatographic analysis are the weight fractions of the species,  $y_i$ , in the system. By definition, the molar concentration,  $C_i$ , of every species in the system can be related to its mass fraction,  $y_i$ , by the following relation:

$$C_i = \frac{y_i W_{hc}}{MW_i V} \quad (4.28)$$

where  $W_{hc}$  is the weight of feedstock injected into the reactor,  $MW_i$  is the molecular weights of the individual specie  $i$  in the system, and  $V$  is the volume of the riser simulator.

To ensure thermodynamic consistency at equilibrium, the temperature dependent equilibrium constant for the reversible reaction was found to be:

$$K_C = \frac{k_1}{k_{-1}} \quad (4.29)$$

which has been calculated from literature as [32]:

$$K_C = \exp \left\{ - \left( \frac{122700 - 126.3T - 2.194 \times 10^{-3}T^2}{RT} \right) \right\} \times 10^5 \text{ Pa} \quad (4.30)$$

Substituting eqs 4.28 and 4.29 into eqs 4.24-4.27, we have the following first order differential equations expressed in terms of weight fractions, which are the measurable variables from gas chromatographic analysis:

$$\frac{dy_{EB}}{dt} = -k_1 \left( y_{EB} - A_1 \frac{y_{ST}y_H}{K_C} \right) \frac{W_C}{V} \exp(-\lambda(1 - y_{EB})) \quad (4.31)$$

$$\frac{dy_{ST}}{dt} = k_1 \left( A_2 y_{EB} - A_3 \frac{y_{ST}y_H}{K_C} \right) \frac{W_C}{V} \exp(-\lambda(1 - y_{EB})) \quad (4.32)$$

$$\frac{dy_{EB}}{dt} = - \left[ k_1 \left( y_{EB} - A_1 \frac{y_{ST}y_H}{K_C} \right) + k_2 y_{EB} \right] \frac{W_C}{V} \exp(-\lambda(1 - y_{EB})) \quad (4.33)$$

$$\frac{dy_B}{dt} = A_4 k_2 y_{EB} \frac{W_C}{V} \exp(-\lambda(1 - y_{EB})) \quad (4.34)$$

$A_1, A_2, A_3$ , and  $A_4$  are lumped constants given as:

$$A_1 = \frac{MW_{EB}W_{hc}}{MW_{ST}MW_HV}$$

$$A_2 = \frac{MW_{ST}}{MW_{EB}}$$

$$A_3 = \frac{W_{hc}}{MW_H V}$$

$$A_4 = \frac{MW_B}{MW_{EB}}$$

The temperature dependence of the rate constants was represented with the centered temperature form of the Arrhenius equation, i.e.,

$$k_i = k_{oi} \exp \left[ -\frac{E_i}{R} \left( \frac{1}{T} - \frac{1}{T_o} \right) \right] \quad (4.35)$$

where  $T_o$  is an average temperature introduced to reduce parameter interaction [79],  $k_{oi}$  is the rate constant for reaction  $i$  at  $T_o$ , and  $E_i$  is the activation energy for reaction  $i$ . Since the experimental runs were done at temperature ranges 350 – 450 °C and 350 – 550 °C for both scheme 2 and scheme 3 respectively,  $T_o$  was calculated to be 400 °C and 450°C.

The above reaction model equations were derived based on the following assumptions:

1. Catalyst deactivation was assumed to be a function of reactant conversion. And, a single deactivation function was defined for all the reactions.
2. The model assumes on catalytic reactions and neglects thermal conversion.
3. The reactor operates under isothermal conditions, justified by the negligible temperature change observed during the reaction.
4. Toluene yield is negligible.

#### **4.2.3.2. Determination of Model Parameters**

The kinetic parameters in equations 4.31-4.34 were estimated using non-linear regression analysis. This was achieved using MATLAB package. The values of the preexponential factors, activation energies and deactivation constants of mechanism I with their corresponding 95% confidence limits are shown in Table 4.15 while those of mechanism II are given in Table 4.17. Correlation matrices of the regression analysis are shown in Tables 4.16 and 4.18 for mechanism I and II respectively, depicting that the interaction between the parameters is at low and moderate level.

The activation energies for styrene formation of the iron doped on organized alumina catalysts obtained by direct and post synthesis methods were apparently lower than those of iron doped on conventional alumina in both schemes 2 and 3. Consequently, it is expected that the decrease in the activation energy for styrene formation, which was observed in iron doped organized alumina catalysts, will cause an increase in the rate of styrene formation which is in agreement with the experimental results. Iron doped organized alumina catalysts obtained by direct synthesis (21%Fe-org.alumina (one-pot)) has the least values of activation energy of 28.3 kJ/mol (6.76 kcal/mol) for styrene formation for the low temperature scheme while a further reduction of activation energy to 9.4 kJ/mol (2.25 kcal/mol) was estimated for the comprehensive temperature scheme. The apparent activation energies obtained for the cracking reaction are higher compared to those of dehydrogenation of EB to St. These estimated values are consistent with the experimental data, which shows higher yields of cracking products only at elevated temperatures. Therefore, high activation energy must be overcome for EB to crack to form benzene which is more than that required for dehydrogenation to form styrene.

From the estimated parameters for both mechanisms I and II, organized alumina favorably supports the active specie and this accounts for the low activation energies as compared to the conventional alumina as support. The activity of all the  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  compared to the  $\text{Mg}_3\text{Fe}_{0.25}\text{Me}_{0.25}\text{Al}_{0.5}$  ( $\text{Me} = \text{Co}, \text{Mn}, \text{Ni}$ ) catalysts shows better performance, which can be attributed to the orderliness of the mesopores of the alumina support. Amongst the  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  catalysts, iron doped organized alumina catalysts showed improvement in the dehydrogenation of EB to styrene, and the direct synthesis method best modifies the catalyst activity and selectivity.

Validity check of the estimated parameters was done by substituting the values in the developed model and then solved numerically using fourth order Runge-Kutta routine. Figure 4.15(A,B) show the reconciliation plots of the model predictions compared to experimental data for schemes 2 and 3 respectively. The plot shows an excellent fit of the experimental data and a regression coefficient,  $r^2$  (0.99), was achieved.

Figure 4.15. Overall comparison between the experimental results and model predictions of all the catalysts for: A) scheme 2, B) scheme 3

## CHAPTER 5

### 5.0 CONCLUSIONS AND RECOMMENDATIONS

#### 5.1 Conclusions

The catalytic dehydrogenation of ethylbenzene into styrene was investigated in a fluidized bed (novel riser simulator) over hydrotalcite and  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  catalysts in the absence of steam. These catalysts were synthesized and characterized and their activities were compared to the commercial catalyst under similar operating conditions. The synthesized catalysts exhibited high surface area and mesopore character. The finely dispersed active species on the catalyst enhanced the catalytic activity and this led to improved efficiency of the process. In addition to catalyst design, change in reactor configuration from conventionally used fixed bed reactor to fluidized bed was explored. Fluidization as a result of high gas recirculation led to a more uniform product distribution due to elimination of temperature gradient which can adversely affect the product quality. Furthermore lowering the reaction temperature and short reaction time limits considerably the occurrence of undesirable reactions due to thermal cracking and suppressed coking on the catalysts.

Among the series of catalysts synthesized for ethylbenzene dehydrogenation  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  catalyst prepared by direct synthesis of loading iron on mesoporous alumina support (21%Fe-meso. $\text{Al}_2\text{O}_3$ ) exhibits the highest activity and selectivity. The results of the XRD, TEM and XPS clearly attribute the presence of highly dispersed active species over large catalyst surface area to have increased the active sites of the catalyst which

play a role in H-abstraction from hydrocarbons especially  $\beta$ -hydrogen from ethylbenzene. Ethylbenzene conversion of 19.5% was achieved with a styrene selectivity of ~94% at reaction temperature of 450 °C and reaction time of 20 s.

Kinetic modeling of the dehydrogenation process was carried out to determine parameters such as activation energy and rate constants. The significance of the model was ascertained by the correlation matrix which indicated low and moderate parameter interaction. The estimated kinetic parameters also had a tolerable confidence limit, and an excellent fit of the experimental data was obtained. These results confirmed the observed product distribution over the catalysts which have been attributed to the catalyst composition.

## **5.2 Recommendations**

Based on the results of this study,

- i. Adsorption kinetics of ethylbenzene dehydrogenation over the hydrotalcite and  $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$  catalyst should be investigated.
- ii. Oxidative dehydrogenation of ethylbenzene to styrene using  $\text{CO}_2$  as a soft oxidant over both catalyst systems.
- iii. Detailed study of catalyst deactivation mechanism.

## **APPENDIX**

**Table A3.1: Retention time of different compounds in the GC**

**GC conditions**

Flow rate of carrier gas (Helium): 20ml/min

Oven Temperature: programmed from 40°C to 250°C in 25 mins

Compounds	*Retention time (min)
Gaseous hydrocarbons	3.019-3.45
Ethylbenzene	13.114
Styrene	15.807
Benzene	8.607
Toluene	11.217
1,2 Diethylbenzene	16.919
1,3 Diethylbenzene	16.452
1,4 Diethylbenzene	16.616

\*Retention may vary slightly at different operating conditions

## NOMENCLATURE

$A_i$	pre-exponential factor for the $i$ th reaction ( $\text{m}^3/\text{kg}$ of catalyst .s)
$C_i$	concentration of specie $i$ in the riser simulator ( $\text{mol}/\text{m}^3$ )
CL	confidence limit
$E_i$	apparent activation energy of the $i$ th reaction ( $\text{kJ}/\text{mol}$ )
$K_c$	equilibrium constant
$k_i$	apparent rate constant for the $i$ th reaction ( $\text{m}^3/\text{kg}$ of catalyst .s)
$k_{oi}$	pre-exponential factor for the $i$ th reaction after re-parameterization ( $\text{m}^3/\text{kg}$ of catalyst .s)
$\text{MW}_i$	molecular weight of specie $i$
$r^2$	correlation coefficient
$r_i$	rate of reaction for species $i$
$R$	universal gas constant ( $\text{kJ}/\text{kmol K}$ )
$t$	reaction time (s)
$T$	reaction temperature (K)
$T_o$	average temperature of the experiment
$V$	volume of the riser ( $45 \text{ cm}^3$ )
$W_c$	mass of the catalyst (0.81 g)
$W_{hc}$	total mass of the hydrocarbon injected the riser (0.162 g)
$y_i$	mass fraction of $i$ th component

### Greek Letters

$\lambda$	catalyst deactivation constant (RC model)
$\alpha$	catalyst deactivation constant (TOS model)

## **Abbreviations**

EB ethylbenzene

Bz benzene

cat catalyst

con conventional

conv conversion

St styrene
